Key words: anthocyanin biosynthesis, autumnal senescence, cDNA microarray, elevated CO₂, LDOX, *Populus*.

• The delay in autumnal senescence that has occurred in recent decades has been linked to rising temperatures. Here, we suggest that increasing atmospheric CO₂ may partly account for delayed autumnal senescence and for the first time, through transcriptome analysis, identify gene expression changes associated with this delay.

• Using a plantation of *Populus × euramericana* grown in elevated [CO₂] (e[CO₂]) with free-air CO₂ enrichment (FACE) technology, we investigated the molecular and biochemical basis of this response. A *Populus* cDNA microarray was used to identify genes representing multiple biochemical pathways influenced by e[CO₂] during senescence. Gene expression changes were confirmed through real-time quantitative PCR, and leaf biochemical assays.

• Pathways for secondary metabolism and glycolysis were significantly up-regulated by e[CO₂] during senescence, in particular, those related to anthocyanin biosynthesis. Expressed sequence tags (ESTs) representing the two most significantly up-regulated transcripts in e[CO₂], *LDOX* (*leucoanthocyanidin dioxygenase*) and *DFR* (*dihydroflavonol reductase*), gave (e[CO₂]/ambient CO₂ (a[CO₂])) expression ratios of 39.6 and 19.3, respectively.

• We showed that in e[CO₂] there was increased autumnal leaf sugar accumulation and up-regulation of genes determining anthocyanin biosynthesis which, we propose, prolongs leaf longevity during natural autumnal senescence.

Introduction

Phenological records suggest that recent global warming has resulted in longer growing seasons. An analysis of over 1700 species showed significant shifts in plant phenology

Dedication: this manuscript is dedicated to David F. Karnosky, who died in 2008, but provided the initial inspiration following our serendipitous observations in the USA and Italy that leaves stayed green for longer in high CO₂.

(Parmesan & Yohe, 2003), including extension of the growing season (Myneni *et al.*, 1997; Menzel & Fabian, 1999; Zhou *et al.*, 2001; Menzel *et al.*, 2006), which has been attributed to rising air temperature (Menzel & Fabian, 1999). On average over the past 35 yr autumnal senescence has been delayed across Europe by 1.3 d per decade (Menzel *et al.*, 2006). However, while a strong correlation exists between atmospheric warming and an earlier spring phenophase, the correlation between warming and a later on-set of the autumn phenophase is very weak (Menzel

et al., 2006). Understanding this process is important, as changing phenology can alter biogeochemical cycling and albedo, both feeding back on climate change (Peñuelas *et al.*, 2009). For example, an extended autumn has been reported to increase carbon storage in the boreal zone of northern latitude forests (Lucht *et al.*, 2002) and in the aspen boreal forests of North America (Chen *et al.*, 1999). It also represents a potential mechanism for adaptation to a changing climate; understanding the genetic and genomic basis of such changes is pertinent to understanding evolutionary mechanisms and, in turn, how forests may be managed and conserved in future.

Over the time period of the Menzel *et al.* (2006) study (1971–2000), atmospheric carbon dioxide has increased by $44 \mu\text{mol mol}^{-1}$ (+13.5%). We have previously shown that elevated atmospheric CO_2 ($e[\text{CO}_2]$) delays autumnal senescence in a forest canopy exposed for 6 yr to $e[\text{CO}_2]$ under free air CO_2 exposure (FACE) (Taylor *et al.*, 2008). At the canopy level, the decline in greenness measured using the normalized difference vegetation index (NDVI) and leaf area index (LAI) were both significantly reduced by $e[\text{CO}_2]$. Also delayed was the decline in leaf chlorophyll, indicating delayed senescence in these trees (Taylor *et al.*, 2008). However, these findings are controversial, as rising $[\text{CO}_2]$ has been shown to shorten (Sigurdsson, 2001), extend (Li *et al.*, 2000; Rae *et al.*, 2006; Taylor *et al.*, 2008) or have no effect (Herrick & Thomas, 2003) on forest senescence.

Natural autumnal senescence is regulated by day length, temperature, light, nitrogen, water supply, plant carbon–nitrogen and source–sink balance (Wingler *et al.*, 2006), the timing of which can be regarded as the result of a trade-off between the conflicting requirements for optimizing the nitrogen and carbon status of the plant (Keskitalo *et al.*, 2005). The strength of the plant's sink for photosynthate can positively influence photosynthetic responses to $e[\text{CO}_2]$ (Bryant *et al.*, 1998; Ainsworth *et al.*, 2004) and also reduce the rate of senescence (Wingler *et al.*, 2004; Kaschuk *et al.*, 2009). Recent studies using girdled sugar maple trees have shown that sugar accumulation in leaves resulted in the formation of anthocyanins (Murakami *et al.*, 2008), and leaves with increased anthocyanin content were associated with a delayed senescence (Schaberg *et al.*, 2008). In poplar, over-expressing an Arabidopsis sucrose phosphate synthase gene resulted in increased leaf sucrose content between August and throughout senescence, which was associated with a delayed senescence (Park *et al.*, 2009). These data indicate the complex interactions between the plants' developmental state, source–sink balance and rate of senescence. Nevertheless, the initiation and a sequence of events during senescence is well conserved. The stimulus for autumnal senescence in *Populus* is a shortening of the photoperiod initiating bud-set, at least for high-latitude trees (Olsen *et al.*, 1997; Keskitalo *et al.*, 2005; Böhlenius *et al.*, 2006; Fracheboud *et al.*, 2009), which is considered an adaptive

trait related to plant fitness (Ingvarsson *et al.*, 2006). Following this, a well characterized sequence of cellular events has been reported (Keskitalo *et al.*, 2005), from chloroplast breakdown, carotenoid and soluble sugar loss to anthocyanin production, a massive 80% nitrogen remobilization and leaf abscission. During this process in poplar, 166 genes were classed as 'most up-regulated', revealing a shift from gene expression associated with anabolism to that of catabolism and an increased role of the mitochondria for energy generation as photosynthesis breaks down (Andersson *et al.*, 2004).

The aim of this research was to understand how exposure to increased atmospheric CO_2 disrupts the process of autumnal senescence and to identify key changes in metabolism and gene expression associated with delayed senescence. We conducted our investigation at the POP/EUROFACE (free air CO_2 enrichment) experiment (Miglietta *et al.*, 2001) where trees had been grown for 6 yr, from planting to canopy closure, in a fully open-air environment at either ambient CO_2 ($a[\text{CO}_2]$) or $e[\text{CO}_2]$ ($550 \mu\text{mol mol}^{-1}$). Conducting this study at a FACE site allowed us to eliminate the potentially confounding problems of sink, nitrogen and water limitation that are common in experiments using other CO_2 fumigation techniques (McLeod & Long, 1999) and are known to influence the rate of senescence. The highly productive, fast-growing trees reported to be non-resource-limited (Liberloo *et al.*, 2009) at the POP/EUROFACE experiment provided the ideal model system in which to investigate the changes in natural autumnal senescence of a forest canopy growing in $e[\text{CO}_2]$. Furthermore, *Populus* is now recognized as a model tree genus (Taylor, 2002; Tuskan *et al.*, 2006; Jansson & Douglas, 2007) enabling genomic resources to be deployed to answer questions of ecological and evolutionary significance on plant response and adaptation to climate change.

Materials and Methods

The POP/EUROFACE site

The POPFACE experiment (9 ha) was situated on a nutrient-rich, clay soil in Tuscania, Italy ($42^\circ 22' \text{N}$, $11^\circ 48' \text{E}$; altitude 150 m asl; <http://www.unitus.it/euroface>). Three species of *Populus* (*P. alba* L. (clone 2AS-11), *P. nigra* L. (clone Jean Pourtet) and *P. × euramericana* (Dode) Guinier (clone I-214)) were grown in the experiment within six experimental plots assigned equally between two treatments of $[\text{CO}_2]$ (a control of ambient CO_2 , $a[\text{CO}_2]$ and elevated CO_2 $e[\text{CO}_2]$ of $550 \mu\text{mol mol}^{-1}$), as described previously (Miglietta *et al.*, 2001; Scarascia-Mugnozza *et al.*, 2006). During the period of this study, trees had been planted for 6 yr, coppiced after 3 yr and exhibited a closed canopy. Canopy characterization and climatic data during this study have been described in detail in Taylor *et al.* (2008) and

only the ambient nitrogen subplots were used in this study, the same treatments as in Taylor *et al.* (2008). A strong chlorosis of the canopies in plots five and six was evident during this study and so these plots were discounted from any further analysis, as described in Liberloo *et al.* (2007). Daytime CO₂ enrichment was provided from bud burst until bud-set except during this study when CO₂ enrichment was continued throughout. The e[CO₂] measured at 1 min intervals was within a 20% deviation from the target concentration of 550 ppm for 94% of the time during the first 3 yr rotation, and for 78% of the time during the second rotation (Liberloo *et al.*, 2009). The leaf sampling regime is described in the Supporting Information (Methods S1) and all sampled leaves were instantly placed in foil, added to a weighted bag and dropped from the canopy to be placed in liquid N₂ (from removal until placing in liquid N₂ was *c.* 10 s).

Canopy level spectral reflectance

Canopy reflectance was measured with a field portable spectroradiometer (GER 3700) (GER, Buffalo, NY, USA; Mod. 3700), and a chlorophyll-specific NDVI (Gitelson & Merzlyak, 1994; Gamon & Surfus, 1999) was calculated as described in Taylor *et al.* (2008). Further details are given in Methods S2.

Microarray hybridization

Total RNA was extracted using the protocol of Chang *et al.* (1993) and as described by Street *et al.* (2006). One hundred micrograms of total RNA was denatured (65°C for 10 min) with 2 µl of anchored oligo(dt)₂₀ primer and this was taken for cDNA synthesis. A reverse transcription master mix was prepared. This consisted of 6 µl 5×-RT-buffer (first-strand buffer), 3 µl of 10 mM Dithiothreitol (DTT), 1 µl of 50× deoxynucleoside triphosphate (dNTP) mix (a mix of dA, dC and dG), and aa-dUTP and dTTP in a ratio of 4 : 1 aa-deoxyuridine-triphosphate (dUTP) : deoxythymidine-triphosphate (dTTP) (all Amersham UK, except for aa-dUTP, which came from Sigma UK), 1 µl RNase inhibitor and 2 µl Superscript™ reverse transcriptase. After overnight synthesis of cDNA at 48°C, the reverse-transcription reaction was inhibited by addition of 10 µl 0.5 M EDTA and any remaining RNA was degraded by the addition of 10 µl 1 M NaOH and heating at 65°C for 15 min. The remaining cDNA was then neutralized with 50 µl of 1 M Hepes (pH 7.5). The cDNA purification was carried out according to the manufacturer's instructions (Qiagen PCR purification kit) with the following exceptions. A phosphate-ethanol wash buffer (PWB: pH 8.0, 5 mM KPO₄) was used instead of buffer PE (Qiagen) and two PWB steps were included. cDNA was then eluted via two elutions each with 30 µl of 0.1 M NaHCO₃ (pH 9.0), and

1 µl of cDNA (60 µl total) was then taken for spectrometric quantification. The purified cDNA (59 µl total) was taken and 35 µl 100 mM sodium acetate (pH 5.2) was added. Under minimal light, purified cDNA was added to an aliquot of CyDye™ ester (Amersham). Cy3 and Cy5 were added to the control and treatment, respectively, and for nearly 50% of the samples this orientation was reversed to account for any dye binding bias. The samples were gently agitated and then left in the dark at room temperature for 2 h. Following a dye-coupled cDNA purification step (using the Qiagen protocol except that an additional buffer PE wash step was included and two repeated elution steps were carried out), the labelled samples were randomly paired between control and treated samples. The total elute containing 200 µl Cy3-and-Cy5 coupled cDNA was concentrated down to 25 µl in a spin concentrator (Eppendorf Concentrator 5301; Eppendorf, Cambridge, UK). The dye-labelled cDNA target (25 µl) was denatured by the addition of 50 µl formamide, 25 µl hybridization buffer (Amersham) was added and the sample was heated at 95°C for 1 min and then chilled on ice.

Microarray slides were purchased from PICME (<http://www.picme.at>) and were estimated to represent *c.* 10 000 predicted gene models in the *P. trichocarpa* genome sequence (Rinaldi *et al.*, 2007). The expressed sequence tags (ESTs) printed on the PICME poplar arrays were produced by INRA-Nancy (Rinaldi *et al.*, 2007), INRA-Orleans (Déjardin *et al.*, 2004) and the University of Helsinki (Brosché *et al.*, 2005) within the framework of the LIGNOME and ESTABLISH programmes. Full MIAME-compliant details of the array content and production can be found at <http://www.picme.at>. An overview of the experimental design is illustrated in Fig. 1. In approach (i) a direct comparison was conducted between replicate senescent samples (18 October) exposed to either elevated CO₂ treatment

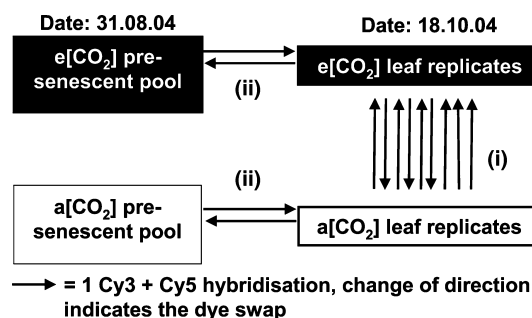

Fig. 1 A schematic representation of the microarray hybridization design. (i) Nine replicate hybridizations are shown for probes obtained from *Populus* leaves sampled on 18 October 2004 with each CO₂ treatment represented in each hybridization. (ii) Two hybridizations are shown for senescence within each CO₂ treatment. The presenescent probe for each treatment was created by pooling probes from seven replicate leaves sampled from within the respective CO₂ environment.

(e[CO₂]) or ambient CO₂ control (a[CO₂]). Of the 12 leaves sampled per treatment on 18 October, RNA of sufficient quality was obtained from nine leaves per treatment. These nine samples were randomly paired so that each CO₂ treatment was represented in each pair. In approach (ii), comparisons between presenescent (31 August) and senescent material were undertaken using a common presenescent reference pool. For the progress of senescence in a[CO₂], the a[CO₂] reference pool was used and this was designated a[CO₂] senescence; in e[CO₂], the e[CO₂] reference pool was used and designated e[CO₂] senescence. Microarray hybridizations were carried out to directly assess the transcriptome changes occurring during senescence in a[CO₂] and e[CO₂]. RNA was extracted individually from presenescent (31 August 2004) leaves and then pooled. The pool for e[CO₂] consisted of seven samples (four from plot one and three from plot four), and the pool for a[CO₂] consisted of seven samples (four from plot two and three from plot three) (Fig. 1). In each pool, 100 µg of total RNA was established using 14.3 µg of total RNA from each replicate leaf.

Prehybridization, hybridization and scanning of the PICME microarray slides, and normalization of the raw expression data are described in Methods S3. Raw image spots were flagged as 'bad' and removed from further analysis if the median signal intensity was less than 256 or equal to 65 535 (saturated). Images were also checked visually and abnormal spots and those far off the indexed spotting grid (dust, salt etc.) were also flagged as bad. Normalized data were then filtered based on *A* value ($(\log_2 R + \log_2 G)/2$) to remove spots with low intensities in both channels (the threshold value for *A* was set to 8.0, equating to a raw intensity of 256 in both channels). The transcript profile data were analysed using linear models with *B* statistics implemented in the LIMMA (Smyth, 2004, <http://bioinf.wehi.edu.au/limma/>) package for the statistical software 'R' (<http://www.r-project.org>) to identify ESTs representing transcripts that may be differentially regulated (Diaz *et al.*, 2003). The model contained only one specified factor for treatment, either e[CO₂] for the 18 October direct comparison between exposure to a[CO₂] and e[CO₂] (approach (i) in Fig. 1) or expression on 18 October for the comparison between the presenescent reference pools and the senescent material (approach (ii) in Fig. 1). Calculated *B*- and *P*-values are adjusted for multiple testing with a false discover rate (FDR) of 0.05 (Benjamini & Hochberg, 1995), which is considered a very conservative statistical analysis for FACE experiments of field-acclimated material (Leakey *et al.*, 2009a). As the influence of senescence on transcript abundance can be very large for some transcripts (Andersson *et al.*, 2004), this conservative statistical analysis was considered appropriate. Transcripts classed as significantly differentially expressed in e[CO₂] compared with a[CO₂] late in senescence (18 October 2004) and during

senescence were those represented by ESTs with a *B*-value ≥ 3 . A *B*-value of zero is equal to a 50 : 50 probability of differential expression whereas a *B*-value of 3 represents approximately 95% certainty of differential expression ($\exp(3)/(1 + \exp(3)) = 0.95$, or 95%). We used a *B*-value of ≥ 3 and a twofold change in mean normalized expression as our threshold for declaring an EST as significantly differentially expressed. Expression levels for gene models were calculated from the mean data of all ESTs representing that model. Sequence annotation was obtained using the tblastx algorithm run by the DOE Joint Genome Institute (JGI, <http://genome.jgi-psf.org>). All microarray data generated have been deposited in the Gene Expression Omnibus (GEO) database as series GSE15874 and platforms GPL8472 and GPL8473.

Analysis of expression changes for genes representing multiple biochemical pathways

Microarray data were further analysed by MapMan (version 2.2.0; Thimm *et al.*, 2004). *Arabidopsis thaliana* orthologue IDs were obtained using the gene model IDs of each EST sequence on the PICME array and the orthologue extractor function in PopGenIE (Sjödin *et al.*, 2009). The mean log₂ ratios for all the *Populus* ESTs representing single *Arabidopsis* orthologue gene models were used in the Mapman pathway analysis. The Wilcoxon rank sum test was used within MapMan to identify any functional group of genes that exhibit a different behaviour in terms of expression profile compared with all the other remaining functional groups. Data were Benjamini Hochberg corrected in MapMan and $P \leq 0.05$ was considered the cut-off for identifying functional groups considered to have a different behaviour in terms of expression profiles. The pathway diagrams for anthocyanin biosynthesis were based on that described for *Arabidopsis* (Solfanelli *et al.*, 2006) and additional information for *Populus* was obtained from Tsai *et al.* (2006).

Real-time quantitative PCR (RT-qPCR)

The selection and validation of the internal reference gene are described in Methods S3. ESTs to be validated were searched by their EST name in the PICME database and the EST information was extracted from NCBI using accession number. Gene model information was downloaded from JGI. Real-time qPCR primers were designed using Beacon Design 5.0 (PREMIER Biosoft International, CA, USA) and the following criteria: *T_m* of 55–60°C and PCR amplicon lengths of 115–160 bp, yielding primer sequences with lengths of 19–22 nucleotides and GC contents of 45–55%. Primers were also designed to amplify close to the 3'-end of the transcripts or EST, and at least one primer of

a pair was designed to cover an exon–exon junction if possible. All primers used in this study were synthesized and desalted by Sigma-Genosys.

The protocols for cDNA synthesis and SYBR Green qPCR are described in Methods S4. The primer pairs used and mean Ct values of the reference gene are also reported in Methods S4.

Leaf biochemistry

Anthocyanin content frozen leaves were ground and 50 mg from each sample was used for analysis according to the method of Martin *et al.* (2002). Data were calculated from the mean of three technical repeats for eight replicate leaves per treatment (four per plot).

Soluble carbohydrates and starch Extraction and measurement of glucose, fructose, sucrose and starch content have been described previously (Rogers *et al.*, 2006). Glucose, fructose and sucrose were extracted from frozen ground material using sequential incubations in ethanol. Starch was extracted from the residual material and converted to glucose. Glucose, fructose, sucrose and the glucose resulting from the starch degradation were then assayed using a continuous enzymatic substrate assay.

Statistical analysis of leaf biochemistry and spectral reflectance

Responses of leaf biochemistry during the progression of autumnal senescence were subjected to general linear model ANOVA (using Minitab[®] 15.1.0.0; Minitab Inc., Philadelphia, PA, USA), with the model: response = block|CO₂ and leaf was considered the unit of replication. No significant block × CO₂ interactions were detected. Responses of canopy spectral reflectance during the progression of autumnal senescence were analysed by a two-way ANOVA with repeated measures in SPSS (SPSS 16.0 for windows) with the model: response = time|CO₂.

Results and Discussion

The trees used in this study exhibited a net increase in photosynthesis (Tricker *et al.*, 2005; Liberloo *et al.*, 2007), increased biomass production (Liberloo *et al.*, 2009), a significantly reduced leaf nitrogen (on a leaf mass basis) (Liberloo *et al.*, 2007) and were considered not to be resource-limited (Liberloo *et al.*, 2009). Taylor *et al.* (2008) established that the field-grown poplar trees in this study exhibit delayed autumnal senescence in response to growth at e[CO₂] (Taylor *et al.*, 2008) and here we unravel the gene expression and biochemical changes that are associated with this response. Fig. 2a shows images across 2 yr for the senescing canopies. A canopy-modified NDVI (a chlorophyll-

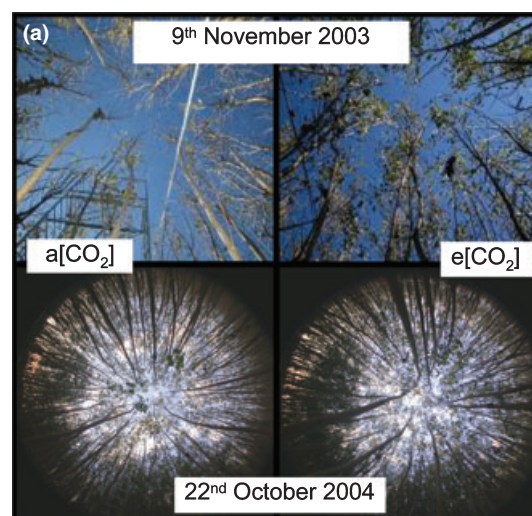

Fig. 2 The influence of elevated [CO₂] (e[CO₂]) on canopy chlorophyll content and leaf anthocyanin content during senescence in *Populus*. (a) Digital images of an ambient CO₂ (a[CO₂]) and an e[CO₂] plot during senescence and on two separate years. (b) The chlorophyll specific normalized difference vegetation index (modified NDVI, where R₇₅₀ and R₇₀₅ are the reflectance at 750 nm and 705 nm respectively) measured over the e[CO₂] (closed bars) and a[CO₂] (open bars) canopies at three time-points through October 2004 (mean ± SE; n = 4). (c) Extractable leaf anthocyanin content in leaves senescing in either e[CO₂] (closed bars) or a[CO₂] (open bars) (mean ± SE; n = 8).

specific NDVI) (Gitelson & Merzlyak, 1994; Gamon & Surfus, 1999) was used to estimate changes in whole-canopy

chlorophyll content during October 2004 (Fig. 2b). As expected during senescence, modified NDVI declined significantly with time ($F_{2,6} = 115.2$, $P \leq 0.001$), and at all time points modified NDVI was significantly greater in $e[\text{CO}_2]$ ($F_{1,3} = 104.1$, $P \leq 0.01$). This indicates that the canopy contained more chlorophyll in $e[\text{CO}_2]$ than in $a[\text{CO}_2]$ during this period and is in agreement with the extracted leaf chlorophyll content reported in Taylor *et al.* (2008). There was no significant interaction between CO_2 treatment and time. Our study provides the first snapshot of what may be occurring within the metabolism of these trees during senescence in $e[\text{CO}_2]$. Initially we focused on genes that exhibited a statistically significant change in regulation in $e[\text{CO}_2]$ during senescence, as evident from the microarray EST data. These data identified a significant up-regulation of key transcripts in anthocyanin biosynthesis. In addition, functional groups of genes were examined which,

together, exhibited a significant change in regulation. These data from direct comparison between an $e[\text{CO}_2]$ and $a[\text{CO}_2]$ late in senescence (18 October) are presented in Fig. 3. Changes in the leaf transcriptome between non-senescent and senescent leaf material in either $e[\text{CO}_2]$ or $a[\text{CO}_2]$ were also examined, and changes in leaf metabolism identified. These data, representing the changes between non-senescent and senescent material, are presented in Figs 4 and 5. Leaf anthocyanin content and soluble and insoluble carbohydrate contents were also measured to support the data identified from the microarrays.

Identifying the genes most significantly influenced by $e[\text{CO}_2]$ late in autumnal senescence

The effect of senescence in $e[\text{CO}_2]$ on transcript abundance for *c.* 10 000 predicted gene models in the *P. trichocarpa*

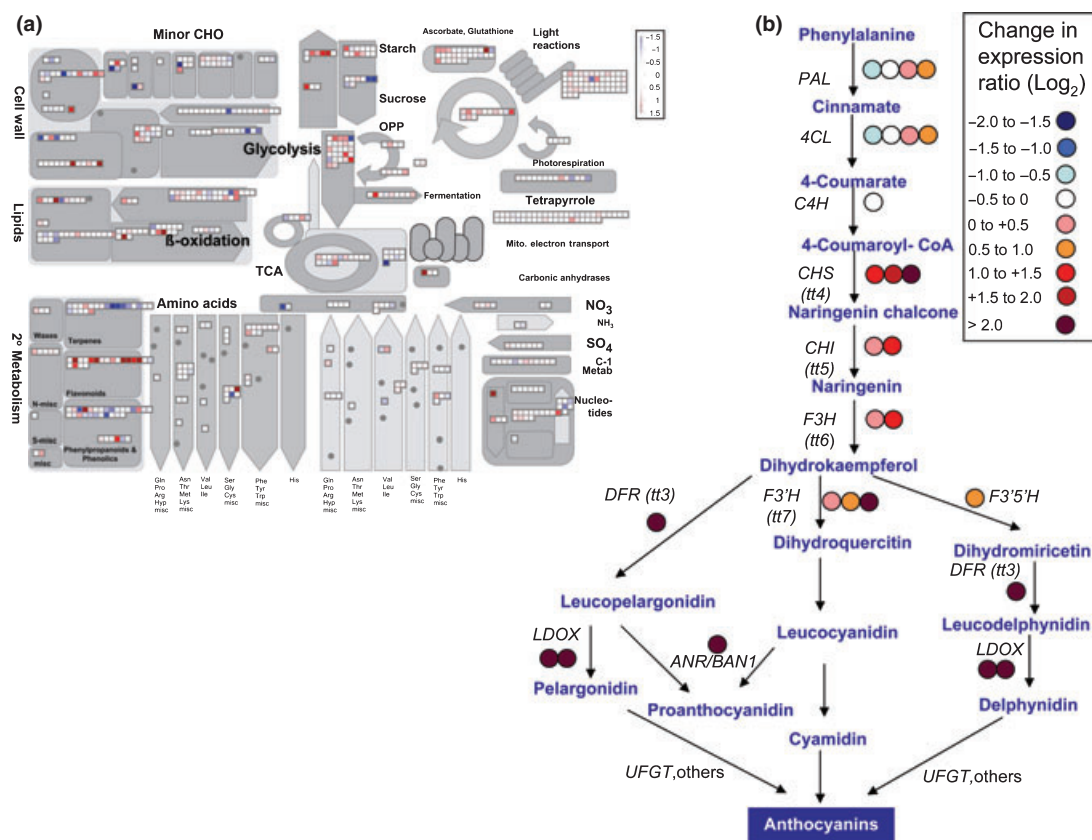

Fig. 3 A representation of transcript abundance from the late senescence (18 October 2004) microarray experiment displaying differential gene expression involved in metabolism (a) and anthocyanin biosynthesis (b). (a) Each coloured square represents the mean log₂ expression data for the Arabidopsis orthologue calculated from the *Populus* expressed sequence tag (EST) expression data. The logarithmic colour scale bar ranges from -1.5 (dark blue, representing a threefold down-regulated gene in elevated $[\text{CO}_2]$ ($e[\text{CO}_2]$)) to $+1.5$ (dark red, representing a threefold up-regulated gene in $e[\text{CO}_2]$). (b) Log₂ transcript abundance data for *Populus* gene models involved in anthocyanin biosynthesis, as a function of ($e[\text{CO}_2]$)/ambient CO_2 ($a[\text{CO}_2]$) expression (the logarithmic colour scale bar ranges from -2.0 to >2.0 , dark blue to dark red). Genes coding for enzymes in this pathway were identified using the *Populus* EST sequence data and annotation and obtaining the Arabidopsis orthologue gene model. Coloured circles represent *Populus* gene models predicted to code for enzymes involved in each metabolic step. Pathway diagrams were constructed using Solfanelli *et al.* (2006) and Tsai *et al.* (2006). The expression data and annotations for (b) are given in the Supporting Information, Table S3.

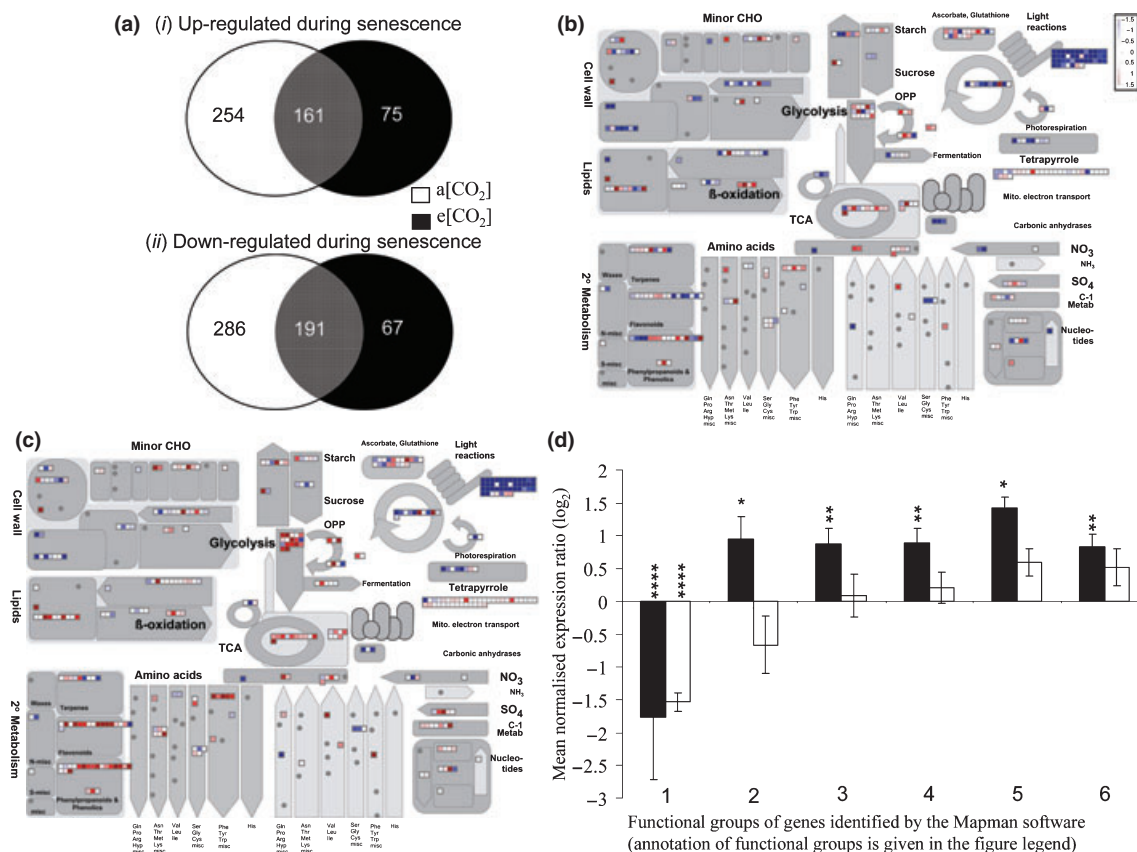

Fig. 4 A representation of transcript abundance during senescence in either ambient CO₂ (a[CO₂]) or elevated [CO₂] (e[CO₂]). (a) Venn diagrams giving the numbers of expressed sequence tags (ESTs) representing significantly differentially expressed genes during senescence up-regulated in common and unique to each [CO₂] (i), and down-regulated (ii). (b, c) MapMan metabolism overview maps representing changes in transcript abundance during senescence in a[CO₂] (b) and e[CO₂] (c) as a function of *Populus* EST expression data (18 October/31 August) within each CO₂ environment averaged by Arabidopsis orthologue. The normalized expression values for all ESTs classed as significantly differentially expressed through the process of senescence in e[CO₂] are reported in Supporting Information, Tables S4 and S5, and those during senescence in a[CO₂] are in Tables S6 and S7. (d) The mean normalized expression ratio (log₂) are for those functional groups that exhibited a significantly (Benjamini Hochberg corrected Wilcoxon rank sum test) different behaviour in terms of expression profiles compared with all the other remaining groups during senescence in e[CO₂] (closed bars). The expression ratio for the same group is given for senescence in a[CO₂] (open bars) and *P*-values are reported as follows: **P* ≤ 0.05, ***P* ≤ 0.01, ****P* ≤ 0.001, *****P* ≤ 0.0001. Functional groups are annotated in MapMan as follows: 1, PS light reactions; 2, secondary metabolism, flavonoids; 3, secondary metabolism, phenylpropanoids; 4, glycolysis; 5, amino acid metabolism, synthesis, aromatic aa, chorismate; 6. TCA cycle.

genome sequence (Rinaldi *et al.*, 2007) was tested using the PICME microarray. Differential gene expression between e[CO₂]- and a[CO₂]-grown leaves was assessed on 18 October during the latter phase of senescence. Canopy leaf area index (LAI) at this time had declined by 43 and 37% from 31 August in a[CO₂] and e[CO₂] treatments, respectively (data not shown). A robust statistical analysis using Bayesian statistics with a FDR of 0.05 was applied to identify the most consistently and significantly differentially expressed transcripts during senescence. This approach is considered by some to be very stringent for FACE experiments (Leakey *et al.*, 2009a). For example, in the study by Taylor *et al.* (2005) zero transcripts would have been classed as significantly differentially expressed at this level of significance. Transcripts represented by 66 ESTs were classed as significantly differentially expressed using a Bayesian log odds

(*B*-stat) cut-off value of ≥ 3. Of these, 15 were significantly up-regulated in e[CO₂], 13 of which were also ≥ twofold up-regulated and these are given in Table S1; 51 were significantly down-regulated, 38 of which were also ≥ twofold down-regulated and these are given in Table S2. The two most significantly differentially expressed transcripts showing the greatest increase in abundance in the e[CO₂] treatment were annotated as *leucoanthocyanidin dioxygenase* (*LDOX*, clone id R71B12) and *dihydroflavonol reductase* (*DFR*, clone id RSH03D11), exhibiting a normalized change in transcript abundance (e[CO₂]/a[CO₂]) of 39.6 (5.3 log₂) and 19.3 (4.3 log₂), respectively (Table S1). The gene models for the two Arabidopsis orthologues of these were identified (*LDOX* gene model at4g22880 and *DFR* gene model at5g42800) and the mean normalized increases in transcript abundance (e[CO₂]/a[CO₂]) for all (not only

Fig. 5 The influence of elevated [CO₂] (e[CO₂]) on gene expression within the anthocyanin biosynthetic pathway and leaf sucrose and starch content during senescence (between 31 August and 18 October). (a) Log₂ expression data for *Populus* gene model from two replicate hybridizations for each CO₂ treatment calculated as ((e[CO₂] 18 October/31 August)/(ambient CO₂ (a[CO₂]) 18 October/31 August)). The pathway diagram was constructed using Solfanelli *et al.* (2006) and Tsai *et al.* (2006). The expression data and annotations for (a) are given in Supporting Information, Table S9. (b, c) Data for leaf sucrose (b) and starch content (c) in both a[CO₂] (open bars) and e[CO₂] (closed bars) ($n = 8$). P -values are reported as follows: * $P \leq 0.05$, ** $P \leq 0.01$, *** $P \leq 0.001$; where no P -value is reported, data were not significant.

those classed as significant) of the *Populus* ESTs showing homology to these Arabidopsis orthologues were 16.7 (4.1 log₂) and 30.2 (4.9 log₂), respectively. These two transcripts code for enzymes in the anthocyanin biosynthetic pathway of *Populus* (Tsai *et al.*, 2006). Correlations between these changes in transcript abundance and leaf anthocyanin content were investigated, with anthocyanin content measured on three occasions in August, October and November. Irrespective of CO₂ treatment, leaf anthocyanin increased over time from late August to early November, as expected during senescence (Keskitalo *et al.*, 2005). Although not statistically significant, anthocyanin content had increased by 413% in e[CO₂] compared with a 342% increase in a[CO₂] between 31 August and 4 November, resulting in a 23% increase in the anthocyanin content by 4 November in e[CO₂] compared with a[CO₂] (Fig. 2c).

Identifying the pathways most significantly influenced by e[CO₂] late in autumnal senescence

Although a relationship between mRNA and protein concentrations can be inferred here for anthocyanin biosynthesis, this may often not be the case (Feder & Walser, 2005). Therefore, by grouping genes into functional categories,

Andersson *et al.* (2004) considered that mean values should represent a good approximation of the relative effort that plants are making to synthesize the proteins of the respective categories. Using the pathway analysis software MapMan (<http://gabi.rzpd.de/projects/MapMan/>), the metabolism overview map was explored against the Arabidopsis TAIR 8 database. Functional groups of genes which together exhibit a statistically significantly different behaviour in terms of expression profiles compared with all the other remaining functional groups were identified. The mean expression data were calculated for each EST passing the quality controls (i.e. not flagged as bad) from the late senescent replicate microarray hybridizations. Of the 13 241 ESTs with expression data, 12 491 exhibited homology with the Arabidopsis genome, and unique Arabidopsis orthologue gene models numbered 4712. The mean log₂ expression data for each Arabidopsis orthologue was imported into MapMan and the functional groups within the metabolism class were analysed (Fig. 3a). The statistically significant differentially regulated functional groups (BINs) were BIN 16.8 secondary metabolism of flavonoid biosynthesis $P \leq 0.02$ (mean normalized expression ratio, $e/a = 4.56$ (2.19 log₂)) and BIN 4 glycolysis $P \leq 0.04$ (mean normalized expression ratio, $e/a = 2.39$

(1.26 log₂). This approach provided further support for up-regulation of secondary metabolism, leading to anthocyanin biosynthesis in e[CO₂] compared with a[CO₂]-grown leaves.

In *Populus* the flavonoid biosynthetic pathway contains increased gene copy numbers for many enzymes when compared with *Arabidopsis* (Tsai *et al.*, 2006) and so the mean expression data for each *Populus* gene model was used. Fig. 3b shows that transcript abundance for enzymes catalysing the biosynthetic pathway from phenylalanine to anthocyanin were generally increased in e[CO₂]. Table S3 gives the expression data for each EST, *Populus* gene models and the *Arabidopsis* orthologues used in Fig. 3(b). The variance for multiple ESTs forming expression data for individual gene models is also given. Although post-transcriptional processes play an important role in regulating metabolism, the greater transcript abundance for nearly the entire pathway (rather than just a small number of enzymes) provides strong evidence for a transcriptionally driven mechanism responding to e[CO₂] and leading to increased anthocyanin biosynthesis. Anthocyanin pigments have a multifaceted protective role in leaves, including protection from UV damage, pathogens, photoinhibition, photo-oxidative stress and scavenging free radicals (Gould, 2004). The increased anthocyanin biosynthesis seen here is consistent with the idea that induction of stress-responsive pathways can extend the viability of senescing cells (Buchanan-Wollaston *et al.*, 2005). Diaz *et al.* (2006) suggest that anthocyanin may influence leaf life span by protecting from photo-oxidative stress, and Schaberg *et al.* (2008) identified a delay in abscission layer formation during autumnal senescence in sugar maple leaves containing increased anthocyanin.

Identifying the genes most significantly influenced by e[CO₂] during the progression of autumnal senescence

To determine whether this shift in metabolism late in senescence was in response to delayed senescence, changes in leaf transcript abundance and selected metabolites were examined. Differential gene expression between the presenescent (31 August) and the senescent canopies (18 October) was investigated (Fig. 4) using RNA from a presenescent reference pool, similar to the approach of Andersson *et al.* (2004). During senescence in a[CO₂], normalized transcript abundance was calculated as (18 October/31 August) and 892 ESTs representing 417 unique *Populus* gene models were significantly differentially expressed (≥ 3 *B*-value and \geq twofold change). In the e[CO₂]-treated canopies, 494 ESTs representing 196 unique *Populus* gene models were classed as significantly differentially expressed; fewer ESTs representing significantly differentially expressed transcripts occurred in e[CO₂] (Fig. 4a). These differences are interesting as they suggest that the senescence transcrip-

tion programme was disrupted by the e[CO₂] treatment. Using a different microarray platform, Andersson *et al.* (2004) identified 201 ESTs representing 166 unique *Populus* gene models as the most up-regulated during senescence in *Populus tremula*. The ESTs representing transcripts exhibiting a twofold change in normalized transcript abundance and a significant *B*-value, and unique to senescence in each CO₂ environment, are reported in Tables S4–S7. Although the Andersson *et al.* (2004) study and the data reported here used different microarray platforms, of the significantly up-regulated transcripts during senescence in e[CO₂], only seven had commonality with Andersson's up-regulated list, whilst in a[CO₂] this numbered 15 (EST data for these are reported in Table S8). Beyond the use of different microarray platforms, the lack of commonality in expression changes during senescence between these studies is a surprise. Species differences, tree environment and leaf position in the tree (upper canopy in this study and lower canopy in Andersson *et al.* (2004)) were also very different which may begin to explain some of the differences seen. The onset of senescence is strongly controlled by changing photoperiod; however, the lack of commonality here may indicate how different biotic and abiotic factors influence the progression of senescence. Systemic differences between these studies (i.e. methodology for declaring EST data as significant) may also account for the lack of commonality. During senescence in e[CO₂], ESTs representing four *Arabidopsis* orthologue gene models in the anthocyanin biosynthetic pathway were among the most abundant (Table S4). These represented the *Arabidopsis* orthologue gene models: at4g22880 (*LDOX*), at5g42800 (*DFR*), at2g37040 (*Phenylalanine ammonia lyase, PAL1*) and at5g05270 (*chalcone-flavanone isomerase, CHI*). The mean normalized increases in transcript abundance in e[CO₂] were 20.26 (4.3 log₂), 12.75 (3.7 log₂), 8.36 (3.1 log₂) and 6.31 (2.7 log₂), respectively, for each of these gene models. Of these gene models, both those expressing the products *LDOX* and *DFR* were among those that were at least fourfold up-regulated and *CHI* was between two- and fourfold up-regulated during the development of bud dormancy in *Populus* (Ruttink *et al.*, 2007).

Identifying the pathways most significantly influenced by e[CO₂] during the progression of senescence

The MapMan software was used to identify functional groups of genes which together exhibited a significantly different behaviour in expression during the progression of senescence in either a[CO₂] or e[CO₂] (18 October/31 August), with data presented in Fig. 4(b)–(d). To identify changes in transcript abundance between senescence in a[CO₂] and senescence in e[CO₂] the sequences for all expression data represented by ESTs existing in both CO₂ environments and passing quality control were taken. These

numbered 7404 ESTs: 7171 showed homology to Arabidopsis and, of these sequences, 2148 were classed as unique Arabidopsis orthologue gene models. Figure 4(b) represents functional groups within the metabolism overview in a[CO₂] and Fig. 4(c) represents groups in e[CO₂]. In both CO₂ environments, these figures show a significant down-regulation of genes involved in the light reactions of photosynthesis, as would be expected. It is notable that the mean down-regulation of this functional group was greater in e[CO₂] than in a[CO₂] (Fig. 4d). It is possible that anthocyanin accumulation results in a stabilization of photosynthetic proteins and pigments in e[CO₂], and thus delayed functional senescence despite induction of the senescence programme at the transcriptional level. During senescence in e[CO₂], the phenylpropanoid and flavonoid biosynthetic pathways were significantly up-regulated (18 October/31 August), 1.84 (0.88 log₂) and 1.93 (0.95 log₂), respectively, while during senescence in a[CO₂] the flavonoid biosynthetic pathway was down-regulated 0.63 (−0.67 log₂) (Fig. 4d). Studies of developing and mature soybean have shown an e[CO₂]-induced increase in transcripts associated with glycolysis (Ainsworth *et al.*, 2006; Leakey *et al.*, 2009b) and data here support this. Both the glycolytic pathway and the TCA cycle were significantly up-regulated during senescence in e[CO₂], as were genes for enzymes of the shikimate pathway leading to chorismate biosynthesis, a precursor for the aromatic amino acids such as phenylalanine (Fig. 4d). Taken together, these data indicate a shift in metabolism between senescence in a[CO₂] and e[CO₂], which appears to coincide with an up-regulation of glycolysis and secondary metabolism. The change in transcript abundance was calculated from EST expression data as a function of (senescence in e[CO₂])/(senescence in a[CO₂]), and the mean *Populus* gene model expression data for the anthocyanin biosynthetic pathway is given in Fig. 5(a). The pathway analysis (Fig. 5a) and data from the EST statistical analysis (Table S4) all indicate an active up-regulation of the anthocyanin pathway during the progress of senescence in e[CO₂] compared with that in a[CO₂]. This supports the transcript data obtained from a direct comparison between CO₂ growth environments late in senescence (Fig. 3b) and the leaf anthocyanin content data (Fig. 2c).

Leaf carbohydrate contents

As photosynthate production declines during the active process of senescence, energy is generated by mitochondrial respiration through processes such as beta-oxidation (Andersson *et al.*, 2004). During senescence in e[CO₂], it could be postulated that metabolism through glycolysis was still sufficient for energy generation, and the products of this metabolism were used in flavonoid biosynthesis. If this were the case, substrate for glycolysis should be present in e[CO₂]-exposed leaves and beta-oxidation could be

expected to be up-regulated in the a[CO₂] leaves. Although not classed as a significantly up-regulated functional group, those genes comprising BIN 11.9.4.2: (lipid metabolism.lipid degradation.beta-oxidation) exhibited increases in mean normalized expression during senescence in a[CO₂] compared with e[CO₂] of 4.20 (2.07 log₂) and 3.07 (1.62 log₂), respectively (data not shown, but extracted from Fig. 4b,c). Sucrose and starch contents were increased in e[CO₂], although this was only significant at two time points and only for sucrose (Fig. 5b,c). A gradual increase in sucrose content was apparent from August to November in e[CO₂] (Fig. 5b). This is in contrast to leaves sampled in the growing season before the onset of senescence and during a preceding year where, in e[CO₂], no accumulation of sucrose or hexoses were observed (Davey *et al.*, 2006). During senescence, starch content declined in all leaves, suggesting that catabolism contributed to the energy requirements of the leaf (Fig. 5c). Glucose and fructose contents are reported in Fig. S1. During senescence, the glucose content of leaves decreased and no significant difference was reported between treatments for either glucose or fructose.

Additional microarray confirmation using RT-qPCR

Transcript abundance data derived from the microarray hybridizations for the pathways reported here are consistent with the findings from leaf biochemical assays of anthocyanin and carbohydrate contents. Real-time qPCR was used to further assess the reliability of the microarray data and particularly to observe the CO₂ influences on *LDOX* transcript abundance. Primers were designed against the sequences of three genes up-regulated and three down-regulated in e[CO₂] on 18 October. The expression of these genes was quantified using RT-qPCR and normalized with *PDF1* as a reference gene. Fig. S2 shows good confirmation between the microarray data and those from RT-qPCR. The relative expression of *LDOX* between the late growing season and late senescence samples was also examined using RT-qPCR. A clear up-regulation of *LDOX* during senescence in e[CO₂] can be seen, with the opposite occurring in a[CO₂] (Fig. S2, inset).

Summary

Once autumnal senescence in *Populus* is initiated by a change in photoperiod (Olsen *et al.*, 1997; Keskitalo *et al.*, 2005; Böhlenius *et al.*, 2006), the balance between reactive oxygen species (ROS) production and ROS scavenging can determine the rate of senescence (McKersie *et al.*, 1988; Buchanan-Wollaston *et al.*, 2003; Gepstein *et al.*, 2003). We have shown that leaf sucrose content was significantly increased by exposure to e[CO₂], while glucose and fructose were not affected, and that this may act as a signal to stimulate the synthesis of anthocyanin. This supports findings in

several contrasting plant species and organs and is supported by work on the mutant *pho3* (Lloyd & Zakhleniuk, 2004). In this sucrose-export mutant (*pho3*), *LDOX* and *DFR* were up-regulated by 190 and 31 times, respectively, again linking leaf sucrose content and anthocyanin biosynthesis. Direct sugar induction of anthocyanin biosynthesis in *Arabidopsis* has also been reported (Teng *et al.*, 2005; Solfanelli *et al.*, 2006). Furthermore, the association between $e[\text{CO}_2]$ and the partitioning of carbon to the synthesis of secondary metabolites was evident in tobacco plants exposed to an $e[\text{CO}_2]$ of 1000 ppm (Matros *et al.*, 2006). The Matros *et al.* (2006) study provides evidence for a direct link between $e[\text{CO}_2]$, an increased leaf C : N ratio and an increased activity of phenylalanine ammonia lyase (PAL), a key enzyme catalysing the first committed step in the biosynthesis of phenylpropanoids, with a concomitant increase of secondary metabolites. Long-lived trees, such as *Populus*, have evolved strategies for defence, dormancy and wood formation that may not be well represented in the genomes of annuals such as *Arabidopsis*. Enzymes involved in the flavonoid biosynthetic pathway leading to anthocyanin production are coded by multiple copy genes in *Populus* and generally single copy genes in *Arabidopsis*, for example, *LDOX* and *DFR* (Tsai *et al.*, 2006). This study further highlights the importance of using *Populus* as a model to study natural autumnal senescence (Jansson & Douglas, 2007) and the open-field environment as essential to gaining a mechanistic understanding of how trees may respond in the natural environment, using fully replicated and designed field experimentation (Taylor *et al.*, 2005).

In conclusion, we have identified an association between delayed autumnal senescence in $e[\text{CO}_2]$, with a change in leaf carbohydrate status, gene expression profiles and anthocyanin content. It is possible that this may be a secondary response to other factors. For example, canopy temperature is often increased during growth in $e[\text{CO}_2]$ at FACE sites, as is evident for soybean (Long *et al.*, 2006). Nevertheless the data reported here begin to identify processes by which climate change can influence plant phenology, although further work will be required to provide evidence of a causal relationship between $e[\text{CO}_2]$, carbohydrate metabolism, anthocyanin biosynthesis and delayed senescence. The most conspicuous change in gene expression was for genes involved in the biosynthetic pathway of anthocyanin; they were strongly and significantly induced in $e[\text{CO}_2]$, resulting in an increased leaf anthocyanin content. The sucrose content of senescing leaves was also increased in $e[\text{CO}_2]$ and we propose that excess carbon in $e[\text{CO}_2]$ is available to be partitioned to carbon-rich secondary metabolites, such as anthocyanin, which provides a protective role in senescing leaves, extending leaf longevity. This CO_2 -stimulated shift in metabolism is consistent with the growth/differentiation balance hypothesis extended by Herms & Mattson (1992)

and observed in forest studies (Harding *et al.*, 2005; Mattson *et al.*, 2005; Cseke *et al.*, 2009). We have begun to identify the genetic mechanisms for adaptation to future CO_2 , but the long-term consequences of such changes for forest ecosystem function and microevolutionary adaptation remain uncertain.

Supporting Information

Additional supporting information may be found in the online version of this article.

Methods S1 Leaf sampling at the POP/EUROFACE site.

Methods S2 Sampling canopy scale spectral reflectance.

Methods S3 Pre-hybridization, hybridization and scanning of microarrays and raw data normalization.

Methods S4 The real-time quantitative PCR (qPCR) protocol.

Fig. S1 Leaf glucose and fructose content during senescence.

Fig. S2 A comparison between the expression ratios of selected genes determined using the microarray data and real-time quantitative PCR (RT-qPCR) data.

Table S1 Expression and annotation details of the 13 expressed sequence tags (ESTs) representing significantly up-regulated ($\geq +3$ *B*-value and \geq twofold) genes in elevated CO₂ on 18 October 2004

Table S2 Expression and annotation details of the 38 expressed sequence tags (ESTs) significantly down-regulated ($\geq +3$ *B*-value and \geq twofold) genes in elevated CO₂ on 18 October 2004

Table S3 Expression and annotation details used for Fig. 3(b)

Table S4 Expression and annotation details of the 75 expressed sequence tags (ESTs) representing significantly up-regulated genes during senescence in elevated CO₂ (18 October/31 August 2004)

Table S5 Expression and annotation details of the 67 expressed sequence tags (ESTs) representing significantly down-regulated genes during senescence in elevated CO₂ (18 October/31 August 2004).

Table S6 Expression and annotation details of the 254 expressed sequence tags (ESTs) representing significantly up-regulated genes during senescence in ambient CO₂ (18 October/31 August 2004)

Table S7 Expression and annotation details of the 286 expressed sequence tags (ESTs) representing significantly down-regulated genes during senescence in ambient CO₂ (18 October/31 August 2004)

Table S8 Expression and annotation details of the expressed sequence tags (ESTs) representing genes classed as significantly up-regulated and in common between this study and the study of Andersson *et al.* (2004)

Table S9 Expression and annotation details used for Fig. 5(a)

About *New Phytologist*

- *New Phytologist* is owned by a non-profit-making **charitable trust** dedicated to the promotion of plant science, facilitating projects from symposia to open access for our Tansley reviews. Complete information is available at www.newphytologist.org.
- Regular papers, Letters, Research reviews, Rapid reports and both Modelling/Theory and Methods papers are encouraged. We are committed to rapid processing, from online submission through to publication 'as-ready' via *Early View* – our average submission to decision time is just 29 days. Online-only colour is **free**, and essential print colour costs will be met if necessary. We also provide 25 offprints as well as a PDF for each article.
- For online summaries and ToC alerts, go to the website and click on 'Journal online'. You can take out a **personal subscription** to the journal for a fraction of the institutional price. Rates start at £151 in Europe/\$279 in the USA & Canada for the online edition (click on 'Subscribe' at the website).
- If you have any questions, do get in touch with Central Office (newphytol@lancaster.ac.uk; tel +44 1524 594691) or, for a local contact in North America, the US Office (newphytol@ornl.gov; tel +1 865 576 5261).
