

# Variation in $a_1$ Saturation in SSC Collider Dipoles\*

Ramesh C. Gupta and Animesh K. Jain

RHIC Project, Brookhaven National Laboratory, Upton, Long Island, NY 11973 USA

## Abstract

Analysis of the variation in the saturation of the skew quadrupole ( $a_1$ ) is presented for the 15m long, 50mm aperture SSC collider dipole magnet prototypes built at BNL. The variations within a magnet are shown to be correlated with *local* top-bottom asymmetry in the iron yoke weight. On the other hand, magnet to magnet variations in the saturation of integral skew quadrupole are shown to be correlated with the geometric  $a_1$ .

## I. INTRODUCTION

Magnets DCA209-DCA213 are a set of 50mm aperture, 15m long SSC collider dipole models built at BNL[1]. The field quality in these magnets is expressed in terms of the normal and skew harmonic coefficients  $b_n$  and  $a_n$  in dimensionless "units" defined by the multipole expansion

$$B_y + iB_x = 10^4 \cdot B_0 \sum_{n=0}^{\infty} (b_n + ia_n) [(x + iy) / R]^n$$

where  $x$  and  $y$  are the horizontal and vertical coordinates,  $B_0$  is the dipole field strength and  $R$  is a "reference radius", chosen as 1cm for these dipoles. A large amount of variation has been observed in the value of the skew quadrupole field coefficient  $a_1$  as a function of current at different axial positions in a single magnet and also from magnet to magnet. As an example, Fig.1 shows the current dependence of  $a_1$  measured with a one meter long measuring coil in magnets DCA209-DCA213. To facilitate comparison, the curves are offset along the y-axis such that the value of  $a_1$  is zero at 2kA for all magnets.

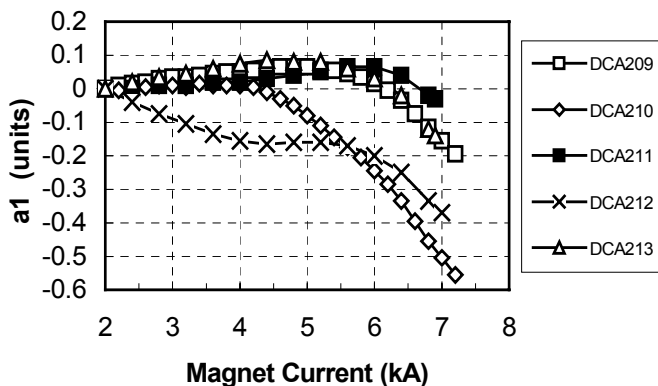

Fig.1 Current dependence of skew quadrupole ( $a_1$ ) in magnets DCA209 to DCA213. The curves are offset such that  $a_1$  at 2kA is zero for all magnets.

The variation with current is commonly referred to as  $a_1$  "saturation" since the major source of this variation is the off-centered placement of the iron yoke in the magnetic cryostat vessel. However, in practice this variation may also include several other sources. In this paper we explain the cause of the measured variations in  $a_1$  saturation and present a simple formula which can be used to predict  $a_1$  saturation in long 50 mm aperture SSC dipole magnets with horizontally split yokes.

## II. SOURCES OF $a_1$ VARIATION

In this section we list some of the sources which may be responsible for the variation in  $a_1$  as a function of current. For each of these sources, we also give estimates of the magnitude of the change,  $\delta a_1$ , between 6600A and 2000A (referred to as "saturation  $a_1$ "). Given below is a brief discussion of some of the sources which may be responsible for the observed  $\delta a_1$ :

### (a) Off-centered yoke in the cryostat :

At high currents the flux lines are not contained in the iron cross section and start leaking outside the yoke. At this stage the magnetic iron in the cryostat vessel provides the additional magnetic path to return the flux lines. However, since the center of cryostat does not coincide with the center of yoke, an up-down asymmetry would be generated in the field at the center of the dipole. The calculations show a noticeable current dependence in  $a_1$  above a primary field of 6.0 Tesla ( $I \sim 6kA$ ) and the computed  $\delta a_1$  is  $\sim -0.2$  unit.

### (b) Difference in the packing factors of the yoke halves :

The packing factor is basically the ratio of the amount of yoke material actually present to the maximum amount of yoke material possible in the design volume. Though the overall difference in the packing factor between the top and bottom yoke halves is well controlled (typically within  $\sim 0.01\%$  in DCA209-213), there may be some local variations along the length of the magnet. The iron weight is measured for each 7.6cm (3") block in the top or bottom yoke. Since the length of the measuring coil is one meter, a top bottom weight difference in the yoke in a one meter region would be seen in the field harmonics. Our 2-d calculations show that a 0.1% higher packing factor in the upper yoke half would give about -0.1 unit of  $\delta a_1$ . This effect is noticeable above 3000A. However, the difference in packing factors is likely to have opposite sign in neighboring packs to maintain a low overall difference in the packing factor. This implies that 2-d calcu-

\* Work Supported by the U.S. Department of Energy.

lations may be over-estimating the effect because in reality the field lines would not only move from bottom to top, but may also move in the axial direction. We will discuss this item in more detail later in Sec.III.

(c) *Off-centered coil in the yoke :*

If the coil center does not match the yoke center, an additional  $\delta a_1$  would be seen. This will also give a geometric  $a_1$ . Our calculations show that for a coil placed 25 $\mu$ m (0.001") above center, there would be an additional  $\delta a_1 \sim +0.1$  unit and the geometric  $a_1$  would be approximately -0.12 unit.

(d) *Difference in the top and the bottom coil sizes :*

A difference between the top and the bottom coil sizes gives a geometric  $a_1$ . The calculations show that if the upper coil half is 25 $\mu$ m larger (which means that the midplane is shifted down by half this amount), the geometric  $a_1$  would be  $\sim +0.7$  unit. It also gives a small additional contribution to the saturation related  $\delta a_1$ , which is about 1% of the geometric  $a_1$ .

There is also a second effect of the coil size difference. It is possible that when there is an initial difference in the size between the top and bottom coil halves, the already displaced coil midplane may shift more as a result of the interaction between the initial mechanical forces and the dynamic ( $I^2$  dependent) Lorentz forces. We have not done the mechanical calculations to compute the amount of this displacement. However, it may be pointed out that merely a 2.5 $\mu$ m additional displacement of the midplane would give a contribution of about 0.14 unit to the observed  $\delta a_1$ .

(e) *Special purpose holes in one yoke pack :*

At about 5m (200 inches) from the lead end, the strain gauges are installed in all the long magnets. In order to bring the wiring out, two 3/8" diameter holes are drilled in one yoke pack from the iron inner radius to the two He bypass holes. This is done only in the bottom half of the magnet. This gives a large local  $a_1$  saturation. Our 2-d estimates suggest that in a 1 meter long measuring coil, an additional  $\delta a_1$  of  $\sim -0.15$  unit should be observed.

(f) *Persistent Currents :*

If an up-down asymmetry is present either in the coil geometry (which also gives geometric  $a_1$ ) or in the coil cables used in the top and bottom coil halves (for example, the cables may have a different  $J_c$ ), an  $a_1$  due to persistent currents would be present. Depending on the amount of asymmetry, the value may be noticeable at 2000A and negligible at 6600A. This would also contribute towards the observed  $\delta a_1$ . We have not done any detailed calculations here, but  $\delta a_1$  due to persistent currents is expected to be within 0.05 unit, based on the measured values of  $a_1$  at 2000A during the up and the down ramps in magnets DCA209-213.

Fig.2  $a_1$  saturation ( $\delta a_1$ ) in DCA209-DCA213 Magnets

### III. $\delta a_1$ VARIATION WITH POSITION

Axial scans have been made in the magnets DCA209 through DCA213 at 2000A and 6600A. It has been found that  $\delta a_1$  varies significantly along the length of a magnet (Fig.2). Amongst the various mechanisms proposed in the previous section, the off-centered yoke in the cryostat and the persistent currents [(a) and (f) in Sec.II] can not account for the variation with position. A difference in the packing factor between the upper and lower yoke halves can be examined most readily from the data on individual yoke block weights. Fig.3 (open boxes) shows the local asymmetry in the top and bottom yoke block weights averaged over the length of the field measuring coil (one meter), as a function of block number (position along the magnet) for the magnet DCA213. The asymmetry is defined as

$$\text{asymmetry} = \frac{\text{wt. of bottom block} - \text{wt. of top block}}{\text{average of top and bottom wts.}} \times 100\%$$

As can be seen from the figure, although the average asymmetry for the entire magnet is nearly zero, there could be a local asymmetry of up to  $\pm 0.1\%$ , when average values over one meter length are considered. The asymmetry is most prominent when the measuring coil center is located around block numbers 60 and 90. Fig.3 also shows the variation of  $\delta a_1$  with position (filled boxes, dashed line). A very good correlation between the yoke asymmetry and  $\delta a_1$  is seen. A similar correlation has been obtained for the magnet DCA212

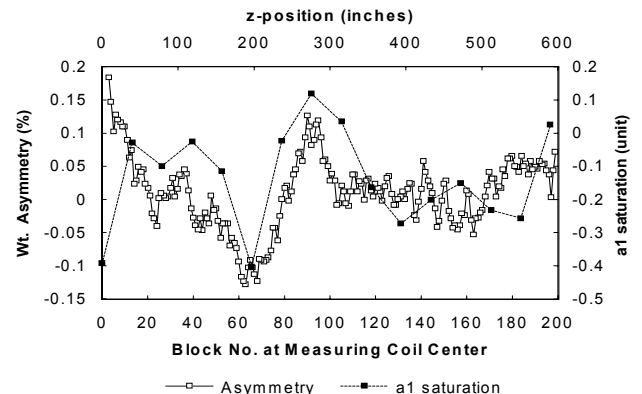

Fig.3 Variation of Top-bottom weight asymmetry and  $\delta a_1$  along the length of the magnet DCA213

also. This shows that the major cause of  $\delta a_1$  variation along the length of the magnet is a local top-bottom asymmetry in the packing factor. It is interesting to note that a similar axial variation in  $b_1$  saturation is seen in the Fermilab magnets, which may have a left-right asymmetry in the packing factor because of the vertically split yoke design.

An examination of the  $a_1$  saturation profiles for all the magnets (Fig.2) reveals that the maximum  $a_1$  saturation is seen at about 200 inches in all the magnets, which is also the location of special purpose holes [Sec.II(e)]. The location and the magnitude of the dips in  $\delta a_1$  in Fig.2 suggest that the holes are contributing to  $\delta a_1$  at about 200 inches. It should be noted that these holes will not be present in the production magnets.

## V. MAGNET TO MAGNET VARIATIONS OF INTEGRAL $\delta a_1$

Since the total weight in the top and bottom yoke halves is well controlled (within  $\sim 0.01\%$ ) in these magnets, we should not see any appreciable magnet to magnet variations in the integral (or the average)  $\delta a_1$ . Table I lists the average values and RMS variations (along length) in  $a_1(2000A)$ ,  $a_1(6600A)$  and  $\delta a_1$  for the magnets DCA209-213. Only the straight section data are considered for the averaging.

Table I shows that contrary to expectations, the integral  $\delta a_1$  does show some magnet to magnet variation ( $\sigma = 0.085$  units). In fact, there is a strong correlation between the integral values of geometric  $a_1$  and  $\delta a_1$ . We suggest the following mechanism as the possible cause for this correlation. A geometric  $a_1$  implies a mechanical difference between the top and the bottom halves of the coil as seen from the midplane. At high current, the asymmetric Lorentz force due to asymmetric coils could modify this coil asymmetry [Sec.II(d)]. The experimental data are examined in Fig.4 which shows the integral  $\delta a_1$  as a function of integral geometric  $a_1$  in magnets DCA209-213. A linear dependence of  $\delta a_1$  on  $a_1$  is seen, which may be parameterized as

$$\delta a_1 = -0.209 + 0.104 \times a_1(2000A)$$

The constant term in the above equation agrees with the value of -0.2 unit calculated from the effect of off-centered yoke in the cryostat in the absence of any other asymmetry [See Sec.II(a)]. The second term gives the dependence of the

**Table I. Integral  $a_1$  and  $\delta a_1$  in magnets DCA209-DCA213**

Magnet	Integral* $a_1(2000A)$	Integral* $a_1(6600A)$	Integral $\delta a_1$
DCA209	$0.26 \pm 0.41$	$0.09 \pm 0.42$	-0.175
DCA210	$-0.23 \pm 0.23$	$-0.47 \pm 0.21$	-0.245
DCA211	$1.76 \pm 0.62$	$1.72 \pm 0.71$	-0.034
DCA212	$-0.19 \pm 0.20$	$-0.42 \pm 0.22$	-0.230
DCA213	$0.61 \pm 0.34$	$0.48 \pm 0.35$	-0.130

\*Error bars refer to RMS variations along the axial position.

Fig. 4 Correlation between geometric and saturation  $a_1$ .

integral  $\delta a_1$  on the geometric integral  $a_1$ . A coefficient of 0.104 implies that there is a  $\sim 10\%$  enhancement in coil asymmetry at 6600A due to Lorentz forces. A similar expression, perhaps with a somewhat different coefficient, is expected for magnets built elsewhere.

## V. CONCLUSIONS

We have examined the possible mechanisms for variation of  $\delta a_1$  in different magnets, and at different locations in a given magnet. There are large variations within a magnet which are correlated to the yoke density variations and position of special purpose holes. A good correlation is also found between the integral values of the geometric  $a_1$  and the saturation induced  $\delta a_1$  in the magnets built so far. Since the systematic value of the geometric  $a_1$  is expected to be zero for the production magnets, this variation would only add slightly ( $\sim 10\%$ ) to the random  $a_1$  at high field. The variation of integral  $\delta a_1$  in these magnets has  $\sigma = 0.085$  units, which is small compared to the axial variations and is much smaller than the SSC tolerance of  $\sigma = 1.25$  units for  $a_1$ . This is achieved because the total weights of the upper and the lower yoke halves are very well controlled.

We thank Peter Wanderer for many useful discussions and a critical review of the manuscript.
