H^- and Heavy Ion Injection Lines for the Booster

R.C. Gupta, R. Damm, Y.Y. Lee and W.T. Weng

In this note we describe the layout and beam optics of the new design of the heavy ion and H^- injection lines for the AGS booster. The earlier design and general reqirements for these beam lines have been described in reference 1 and reference 2. The major design changes come due to the fact that now the heavy ions will be injected in the straight section C3 instead of A3. In the earlier plan the heavy ion line would have gone through the old 50 Mev Linac staging area. In the new plan we propose to use the existing tunnel for the 200 MeV H^- line from the LINAC to the AGS. The heavy ions will enter in it from the AGS tunnel. The overall layout of the two injection lines is shown in Fig 1. The layout near the booster area is shown in more detail in Fig 2. The positions of various dipoles, quadrupoles and other elements is also shown in this figure. As shown in Fig 2, there will be a common tunnel for both lines in the intermediate area of the booster and the 200 Mev H^- line to the AGS. The optics has been designed in such a way that the two beam lines produces a 10 feet long component free section in the intermediate tunnel. This space will be used for a concrete wall which would provide a radiation shielding between the booster and the linac. The minimum separation between the two lines at any place will be about 3 feet.

The H^- line will always remain at the booster elevation, which is 75 feet above the sea level. The heavy ion line, however, has to go through different elevations during its course from the 69 degree bend (located in the old south west experiment area of the AGS) to the injection point in the booster. The elevation of this line at the 69 degree bend point is 85 feet, in the AGS tunnel will be 76.18 feet, in the present 200 MeV H^- line tunnel will be 78 feet and after the last dipole in the intermediate tunnel will be 75 feet. Fig 2a shows the beam line elevations from HITL to all the way into the Booster. A small tilt in various horizontal bends will provide the required vertical bend to pitch the line up or down at the above

mentioned locations. In the following two sections, these two lines will be described in little more detail.

The H^- Injection Line

The proposed H^- injection line to the booster will use the first five quadrupoles of the present H^- injection line for the AGS. A kicker magnet, imparting a 7.5 degree deflection, will be installed in the present line to guide the H^- beam towards the new injection line. The new beam line will have four dipoles, each 1.3 meter long and giving a deflection of 31.5413 degrees with a field strength of 9.1 kG. Richard Thomas has computed the loss due to electromagnetic stripping in these magnets (Please see reference 3). The loss is about 0.01%, which can be tolerated here. We cluster the first three dipoles quite close to each other and put the last one far away. There are two quads between the last two dipoles which have been put very close to the either dipoles to create a component free 10 feet long section for radiation shielding. There are six quadrupoles between the last dipole of this line and the first magnet of the booster ring. These six quads will be used to experimentally determine the phase ellipse parameters of the beam at the injection point to achieve the highest intensity of the accelerated protons. In the final design described in this note, the phase space ellipses and the dispersion functions of the injected beam are matched to the lattice parameters of the booster lattice at the injection point. The H^- ions will enter in the booster through the displaced yoke of the dipole magnet MDC5. The injection line has been designed so that the injected H^- beam at the stripper foil comes parallel to the circulating proton beam and has a separation of 2" form it. The actual position of the stripper foil and the injection point can be changed later to empirically determine the best injection and operation parameters.

The position of various dipoles and quadrupoles in this beam line, in both booster and AGS coordinates, is given in Fig 3. The input to the computer program MAD, which has been used in the final design of this line, is given in Fig 4. The input file also gives the

value of length and strength of all elements used in this line. The final optics of this beam line can be seen in Fig 5 where we have plotted the variations in the lattice functions (BETAX, BETAY and XP). We use the beam ellipse parameters of the 200 MeV beam just after the last LINAC tank (Tank T9) to design the rest of the beam line. The beam size at any point remains well within the 4" aperture of the quadrupoles. The MAD output giving the lattice functions of the injected beam in the H^- injection line is given in Fig 6.

The Heavy Ion Injection Line

In this note we describe a part of the heavy ion injection line. However, this is the most crucial part in designing beam optics since this part does the matching of the dispersion function (and also its derivative) and provides a 10 feet long component free section for the radiation shielding. In fact, had we not found a solution fulfilling these requirements, we would have to continue with the older design where the beam was injected in the straight section A3. The beam line in question is from the tunnel of the present 200 MeV H^- line (to AGS) to the injection point in the booster. This beam line is shown in Fig 2.

This beam line has three dipople magnets and one electrostatic septum. Each magnet has a length of 0.9 meter and gives a deflection of 40 degrees. The first two magnets (HIDA and HIDB) bends the beam in clockwise direction and the last (HIDC) in counter clockwise direction. The magnets, HIDB and HIDC, are tilted by 6.31228 degrees to produce the 3 feet downward pitching. The electrostatic septum is 3.2 meter long and gives a deflection of 20.6329 degrees in the counter clockwise direction.

The position of various dipoles and quadrupoles in the heavy ion beam line, in both booster and AGS coordinates, is given in Fig 7. The input to the computer program MAD, which has been used in the final design of this line, is given in Fig 8. The input file also gives the value of length and strength of all elements used in this

line. The final optics of this beam line can be seen in Fig 9 where we have plotted the variations in the lattice functions (BETAX, BETAY, XP and YP). The beam size at any point remains well within the 4" aperture of the quadrupoles. The MAD output giving the lattice functions of the injected beam in this injection line is given in Fig 10.

In the design described in this note, the phase space ellipses and the horizontal dispersion function (together with its derivative) of the injected beam are matched to the lattice parameters of the booster lattice at the injection point. The vertical dispersion function, however, could not be matched completely and it comes out to be about 0.4 meter at the injection point. In these calculations we have used the MAD version 4.03. This version does not deal with the electrostatic septum. Now the higher version of this program are available in the laboratory and they will be used in future computations to describe the optics of the electrostatic septum correctly. In the present run we assumed that the electrostatic septum behaves the same way as the magnetic septum for giving the change in XP and the change in the XP' due to it will be twice as that of the magnetic element. In any case, the eight quadrupoles between the magnets HIDB and HIDC, should be sufficient to produce any solution in the vicinity of the one we are presenting in this note.
